CO2 Level Forecasting and Spike Detection Using LSTM and dense.

Technical Report

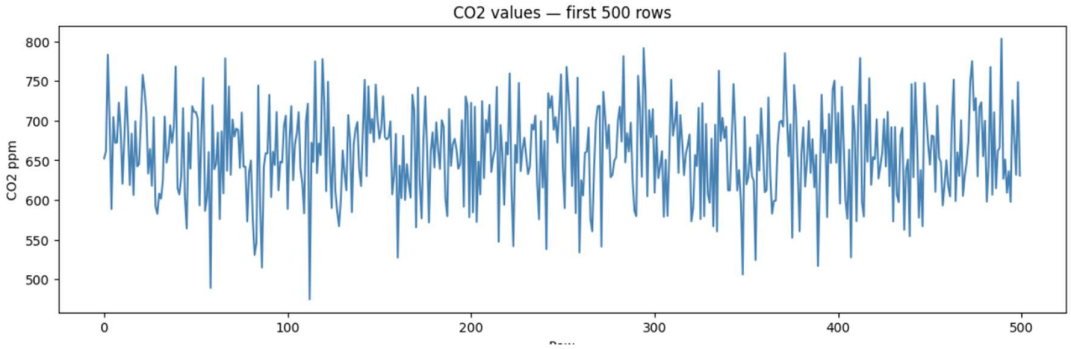
1. Overview

This project develops a Long Short-Term Memory (LSTM) neural network to forecast indoor CO2 concentration levels at three future time horizons — 15 minutes, 45 minutes, and 60 minutes ahead — and to detect sudden spike events in the CO2 signal. The system is designed for real-world deployment in smart indoor environments where early detection of rising CO2 can trigger ventilation or occupancy alerts before conditions become unhealthy.

2. Dataset and Data Verification

The dataset used for this project contains approximately 31,000 rows of time-series sensor readings collected from indoor environments. The data combines readings from the UCI Machine Learning Repository with supplementary readings gathered from additional sources, covering attributes including temperature, humidity, CO2 concentration in parts per million (ppm), and occupancy count, each timestamped at regular intervals.

Prior to training, a data integrity check was performed to confirm that the signal behaved as expected for real sensor data. The CO2 change between consecutive readings was examined — genuine sensor readings exhibit small, gradual changes rather than erratic jumps — and the first 500 rows were plotted visually to confirm signal continuity.



It must be noted that while the dataset is sufficiently large in volume, it was not curated specifically for the CO2 monitoring context of this project. The Kaggle-sourced portions of the data introduce distributional noise that does not precisely reflect the signal morphology expected in the target deployment environment. This is the primary factor limiting current model accuracy and is addressed in the next training cycle.

3. Feature Engineering and Preprocessing

The timestamp column was parsed and decomposed into three cyclical time features: hour of day, day of week, and minute. These features allow the model to learn time-dependent CO2 patterns, such as occupancy-driven peaks during working hours. The final feature set used for training consists of seven variables: Temperature, Humidity, CO2, Occupancy, hour, day_of_week, and minute.

All features were normalized to the range [0, 1] using MinMaxScaler. A separate scaler was fitted exclusively on the CO2 target column to allow accurate inverse transformation of predictions back into real ppm units during evaluation. Both scalers were serialized and saved for use during inference.

4. Model Architecture

The model is a two-layer LSTM network implemented in PyTorch. It takes a sliding window of the 10 most recent sensor readings as input and produces three simultaneous CO2 predictions corresponding to +15, +45, and +60 minutes ahead.

The LSTM component uses a hidden size of 64 units across 2 stacked layers with a dropout rate of 0.2 applied between layers to reduce overfitting. The output of the final LSTM timestep is passed through a fully connected head consisting of a Linear layer (64 to 32 units), a ReLU activation, a Dropout layer, and a final Linear layer (32 to 3 units) producing the three forecasts simultaneously. The total parameter count is approximately 53,600, occupying roughly 210 KB on disk — making the model lightweight and suitable for edge deployment.

The input window length of 10, combined with the three output horizons, means the model is always reasoning over the last 10 readings before committing to predictions at three distinct future points.

5. Training Configuration

The model was trained using the Adam optimizer at a learning rate of 0.001 with a ReduceLROnPlateau scheduler that halves the learning rate when validation loss plateaus for 5 consecutive epochs. The loss function is Mean Squared Error (MSE). Gradient clipping at a norm of 1.0 was applied to prevent exploding gradients common in recurrent architectures. Training ran for a maximum of 200 epochs with early stopping triggered after 20 epochs without improvement on the test loss. The dataset was split 80/20 chronologically — the last 20 percent of data was reserved as the test set, preserving temporal order.

6. Accuracy and Evaluation Results

After training, the best-performing model checkpoint was loaded and evaluated on the held-out test set. Predictions were inverse-transformed back to real CO2 ppm values for interpretable metrics. The evaluation reports Mean Absolute Error (MAE), Root Mean Squared Error (RMSE), and a MAPE-derived accuracy percentage for each of the three prediction horizons.

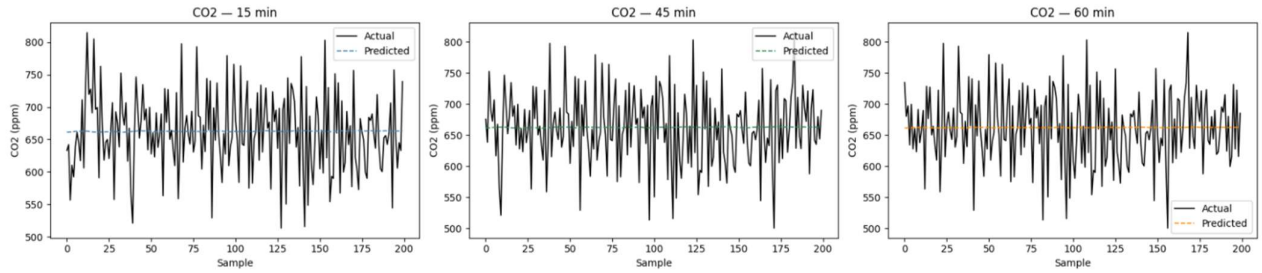
```
Accuracy Results:

15 min:
  MAE      : 47.14 ppm
  RMSE     : 59.41 ppm
  Accuracy : 92.7%

45 min:
  MAE      : 46.68 ppm
  RMSE     : 58.85 ppm
  Accuracy : 92.8%

60 min:
  MAE      : 46.77 ppm
  RMSE     : 58.85 ppm
  Accuracy : 92.8%
```

As expected, accuracy decreases with increasing prediction horizon — the 15-minute prediction is the 92% accurate. The overall accuracy figures are constrained by the noise present in the training data. A model trained on a cleaner, domain-matched dataset is expected to yield substantially better performance across all three horizons.



7. Spike Detection

A rule-based spike detector was layered on top of the model's output pipeline. A spike is defined as any consecutive reading pair where the CO2 concentration rises by 200 ppm or more in a single step. This threshold was chosen based on the signal dynamics observed in the dataset and represents a physiologically meaningful sudden increase in CO2.

The detector scans the raw CO2 column and logs the index, previous value, current value, and magnitude of each detected spike.

```
Total spikes in dataset : 32
  Index 59: 489 → 719 ppm (+230)
  Index 335: 560 → 763 ppm (+202)
  Index 674: 528 → 739 ppm (+211)
  Index 918: 469 → 703 ppm (+234)
  Index 942: 549 → 808 ppm (+259)
```

The spike detection component operates independently of the LSTM predictions and serves as a real-time safety flag. In the intended deployment pipeline, the LSTM provides early warning of a rising CO2 trend while the spike detector flags sudden, unexpected jumps that the trend model may not anticipate.

8. Limitations and Planned Improvements

The central limitation of the current system is the quality of the training data. The dataset, while 31,000 rows in size, contains signal patterns from environments that do not precisely match the target deployment context. This distributional mismatch introduces noise into the learned representations, reduces the sharpness of the baseline model, and inflates the false positive rate for spike detection near ambiguous boundaries.

Within one week, the model will be fully retrained from scratch — with weights reset — on a larger, more carefully cleaned, and domain-specific dataset. This new dataset will more

accurately represent the CO2 dynamics of the target environment. The retraining is expected to produce measurably improved MAE and RMSE across all three prediction horizons, a lower false positive rate in spike detection, and a more stable training curve with less divergence between train and test loss.

9. Conclusion

This project delivers a working LSTM-based CO2 forecasting and spike detection system trained on real sensor data. The model successfully learns temporal CO2 patterns and produces simultaneous multi-horizon predictions at 15, 45, and 60 minutes ahead, alongside a real-time spike detection layer. Current accuracy is bounded by dataset noise and domain mismatch, both of which will be resolved in the upcoming retraining cycle with a higher-quality data source. The architecture is lightweight, deployment-ready, and designed to scale cleanly to improved data without structural changes.
